### Abstract

This tutorial illustrates the imputation of incomplete multilevel data with the R package **mice**. Our scope is only simple multilevel models, to show how imputation can yield less biased estimates from incomplete clustered data. More complex models can be accommodated, but are outside the scope of this paper.

*Keywords:* missing data, multilevel, clustering, **mice**, R.

---

## 1. Introduction

Many datasets include individuals that are clustered together, for example in geographic regions, or even different studies. In the simplest case, individuals (e.g., students) are nested

Table 1: Concepts in multilevel methods

Concept	Details
Sample unit	Units of the population from which measurements are taken in a sample.
Hierarchical levels	Data are grouped into clusters at different levels, observations belonging to the same cluster are expected to share certain characteristics.
Fixed effect	Effects that are constant across all sample units, e.g. something that researchers control for and can repeat, such as the administration of a drug.
Random effect	Effects that are a source of random variation in the data, and whose levels are not fully sampled. e.g. individuals are drawn from a population of hospitals, here it is not possible to sample all hospitals but drug effects could vary between hospitals.
Mixed effect	Includes fixed and random effects, e.g. the fixed effect would be the treatment effect of a drug and the random effect would be the ID of the hospital where the patient is treated. Multilevel models typically accommodate for variability by including a separate group mean for each cluster e.g random intercept on hospitals. In addition to random intercepts, multilevel models can also include random coefficients and heterogeneous residual error variances across clusters (see e.g. @gelm06, @hox17 and @jong21).
ICC	The variability due to clustering is often measured by means of the intraclass coefficient (ICC). The ICC can be seen as the percentage of variance that can be attributed to the cluster-level, where a high ICC would indicate that a lot of variability is due to the cluster structure.
Stratified intercept	

within a single cluster (e.g., school classes). More complex clustered structures may occur when there are multiple hierarchical levels (e.g., students in different schools or patients within hospitals within regions across countries), or when the clustering is non-nested (e.g., electronic health record data from diverse settings and populations within large databases). With clustered data we generally assume that individuals from the same cluster tend to be more similar than individuals from other clusters. In statistical terms, this implies that observations from the same cluster are not independent and may in fact be correlated. If this correlation is left unaddressed, estimates of  $p$  values, confidence intervals even model parameters are prone to bias (Localio, Berlin, Ten Have, and Kimmel 2001). Statistical methods for clustered data typically adopt hierarchical models that explicitly describe the grouping of observations. These models are also known as ‘multilevel models’, ‘hierarchical models’, ‘mixed effect models’, ‘random effect models’, and in the context of time-to-event data as ‘frailty models’. Table 1 provides an overview of some key concepts in multilevel modeling.

	cluster	$X_1$	$X_2$	$X_3$	...	$X_p$
1	1			NA		
2	1					
3	2		NA			
4	2		NA	NA		
5	3					
...						
n	N					

Figure 1: Sporadic missingness in multilevel data

### 1.1. Missingness in multilevel data

As with any other dataset, clustered datasets may be impacted by missingness in much the same way. Several strategies can be used to handle missing data, including complete case analysis and imputation. We focus on the latter approach and discuss statistical methods for replacing the missing data with one or more plausible values. Imputation separates the missing data problem from the analysis and the completed data can be analyzed as if it were completely observed. It is generally recommended to impute the missing values more than once to preserve uncertainty due to missingness and to allow for valid inferences (c.f. Rubin 1976).

With incomplete clustered datasets we can distinguish between two types of missing data: sporadic missingness and systematic missingness (Resche-Rigon, White, Bartlett, Peters, and Thompson 2013). Sporadic missingness arises when variables are missing for some but not all of the units in a cluster (Van Buuren 2018; Jolani 2018). For example, it is possible that test results are missing for several students in one or more classes. When all observations are missing within one or more clusters, data are said to be systematically missing.

Imputation of missing data requires consideration of the mechanism behind the missingness. Rubin proposed to distinguish between data that are missing completely at random (MCAR), data that are missing at random (MAR) and data that are missing not at random (MNAR; see Table ??). For each of these three missingness generating mechanisms, different imputation strategies are warranted (Yucel (2008) and Hox, van Buuren, and Jolani (2015)). We here consider the general case that data are MAR, and expand on certain MNAR situations.

Table 2: Concepts in missing data methods

Concept	Details
MCAR	Missing Completely At Random, where the probability to be missing is equal across all data entries
MAR	Missing At Random, where the probability to be missing depends on observed information
MNAR	Missing Not At Random (MNAR), where the probability to be missing depends on unrecorded information, making the missingness non-ignorable

Concept	Details
	(Rubin 1976; Meng 1994).

## 1.2. Aim of this paper

This paper serves as a tutorial for imputing incomplete multilevel data with **mice** in R. **mice** has become the de-facto standard for imputation by chained equations, which iteratively solves the missingness on a variable-by-variable basis. **mice** is known to yield valid inferences under many different missing data circumstances (Van Buuren 2018).

We provide practical guidelines and code snippets for different missing data situations, including non-ignorable mechanisms. For reasons of brevity, we focus on multilevel imputation by chained equations with **mice** exclusively; other imputation methods and packages (see e.g. Audigier, White, Jolani, Debray, Quartagno, Carpenter, van Buuren, and Resche-Rigon 2018, and Grund, Lüdtke, and Robitzsch (2018)) are outside the scope of this tutorial. Assumed knowledge includes basic familiarity with the **lme4** notation for multilevel models (see Table ??).

We illustrate imputation of incomplete multilevel data using three case studies:

- **popmis** from the **mice** package (simulated data on perceived popularity,  $n = 2,000$  pupils across  $N = 100$  schools with data that are MAR, van Buuren and Groothuis-Oudshoorn 2021);
- **impact** from the **metamisc** package (empirical data on traumatic brain injuries,  $n = 11,022$  patients across  $N = 15$  studies with data that are MAR, Debray and de Jong 2021);
- **obesity** from the **micemd** package [simulated data on obesity,  $n = 2,111$  patients across  $N = 5$  regions with data that are MNAR].

For each of these datasets, we discuss the nature of the missingness, choose one or more imputation models and evaluate the imputed data, but we will also highlight one specific aspect of the imputation workflow.

This tutorial is dedicated to readers who are unfamiliar with multiple imputation. More experienced readers can skip the introduction (case study 1) and directly head to practical applications of multilevel imputation under MAR conditions (case study 2) or under MNAR conditions (case study 3).

## 1.3. Setup

Install non-CRAN packages if necessary:

```
R> devtools::install_github("amices/ggmice")
```

Set up the R environment and load the necessary packages:

```
R> set.seed(2022)           # for reproducibility
R> library(mice)             # for imputation
R> library(miceadds)        # for additional imputation routines
R> library(ggmice)          # for incomplete/imputed data visualization
R> library(ggplot2)         # for visualization
R> library(dplyr)           # for data wrangling
R> library(lme4)            # for multilevel modeling
R> library(mitml)           # for multilevel parameter pooling
R> library(micemd)          # for imputation cf. heckman models
R> library(metamisc)        # for case study data
```

## 2. Case study I: popularity data

In this section we will go over the different steps involved with imputing incomplete multilevel data with the R package `mice`. We consider the simulated `popmis` dataset, which included pupils ( $n = 2000$ ) clustered within schools ( $N = 100$ ). The following variables are of primary interest:

- `school`, school identification number (clustering variable);
- `popular`, pupil popularity (self-rating between 0 and 10; unit-level);
- `sex`, pupil sex (0=boy, 1=girl; unit-level);
- `texp`, teacher experience (in years; cluster-level).

The research objective of the `popmis` dataset is to predict the pupils' popularity based on their gender and the experience of the teacher. The analysis model corresponding to this dataset is multilevel regression with random intercepts, random slopes and a cross-level interaction. The outcome variable is `popular`, which is predicted from the unit-level variable `sex` and the cluster-level variable `texp`:

```
R> mod <- popular ~ 1 + sex + (1 | school)
```

Load the data into the environment and select the relevant variables:

```
R> popmis <- popmis[, c("school", "popular", "sex")]
```

First we plot the pattern of missing data within categories of the relevant variables. Plot the missing data pattern:

```
R> plot_pattern(popmis)
```

The missingness is univariate and sporadic, which is illustrated in the missing data pattern in Figure 2.

To develop the best imputation model for the incomplete variable `popular`, we need to know whether the observed values of `popular` are related to observed values of other variables. Plot the pair-wise complete correlations in the incomplete data:

Figure 2: Missing data pattern in the popularity data

```
R> plot_corr(popmis)
```

This shows us that **sex** may be a useful imputation model predictor. Moreover, the missingness in **popular** may depend on the observed values of other variables.

```
R> # ggmmice(popmis, aes(sex)) +
R> #   geom_histogram(fill = "white") +
R> #   facet_grid(. ~ is.na(popular), scales = "free", labeller = label_both)
R>
R> ggplot(popmis, aes(y = popular, group = sex)) +
+   geom_boxplot() +
+   theme_classic()
```

### *Imputation ignoring the cluster variable (not recommended)*

The first imputation model that we'll use is likely to be invalid. We do not use the cluster identifier `school` as imputation model predictor. With this model, we ignore the multilevel structure of the data, despite the high ICC. This assumes exchangeability between units. We include it purely to illustrate the effects of ignoring the clustering in our imputation effort.

Create a methods vector and predictor matrix for `popular`, and make sure `school` is not included as predictor:

```
R> meth <- make.method(popmis) # methods vector
R> pred <- quickpred(popmis)   # predictor matrix
R> plot_pred(pred)
```

Impute the data, ignoring the cluster structure:

```
R> imp <- mice(popmis, pred = pred, print = FALSE)
```

Analyze the imputations:

```
R> fit <- with(imp,
+             lmer(popular ~ 1 + sex + (1 | school)))
```

Print the estimates:

```
R> testEstimates(as.mitml.result(fit), extra.pars = TRUE)
```

Call:

```
testEstimates(model = as.mitml.result(fit), extra.pars = TRUE)
```

Final parameter estimates and inferences obtained from 5 imputed data sets.

	Estimate	Std.Error	t.value	df	P(> t )	RIV	FMI
(Intercept)	5.012	0.295	16.994	4.362	0.000	22.587	0.969
sex	0.695	0.251	2.768	4.287	0.047	28.390	0.975

	Estimate
Intercept~~Intercept school	0.266
Residual~~Residual	1.035
ICC school	0.208

Unadjusted hypothesis test as appropriate in larger samples.

### *Imputation with the cluster variable as predictor (not recommended)*

We'll now use `school` as a predictor to impute all other variables. This is still not recommended practice, since it only works under certain circumstances and results may be biased (Drechsler 2015; Enders, Mistler, and Keller 2016). But at least, it includes some multilevel aspect. This method is also called 'fixed cluster imputation', and uses N-1 indicator variables representing allocation of N clusters as a fixed factor in the model (Reiter, Raghunathan, and Kinney 2006; Enders et al. 2016). Colloquially, this is 'multilevel imputation for dummies'.

```
R> # adjust the predictor matrix
R> pred["popular", "school"] <- 1
R> plot_pred(pred)
```

```
R> # impute the data, cluster as predictor
R> imp <- mice(popmis, pred = pred, print = FALSE)
```

Analyze the imputations:

```
R> fit <- with(imp,
+             lmer(popular ~ 1 + sex + (1 | school)))
```

Print the estimates:

```
R> testEstimates(as.mitml.result(fit), extra.pars = TRUE)
```

Call:

```
testEstimates(model = as.mitml.result(fit), extra.pars = TRUE)
```

Final parameter estimates and inferences obtained from 5 imputed data sets.

	Estimate	Std.Error	t.value	df	P(> t )	RIV	FMI
(Intercept)	4.915	0.217	22.642	4.926	0.000	9.110	0.926
sex	0.975	0.283	3.444	4.250	0.024	32.504	0.978

	Estimate
Intercept~~Intercept school	0.351
Residual~~Residual	1.153
ICC school	0.233

Unadjusted hypothesis test as appropriate in larger samples.

*Imputation with multilevel model*

```
R> # adjust the predictor matrix
R> pred["popular", "school"] <- -2
R> plot_pred(pred)
```

```
R> # impute the data, cluster as predictor
R> imp <- mice(popmis, pred = pred, print = FALSE)
```

Analyze the imputations:

```
R> fit <- with(imp,
+             lmer(popular ~ 1 + sex + (1 | school)))
```

Print the estimates:

```
R> testEstimates(as.mitml.result(fit), extra.pars = TRUE)
```

Call:

```
testEstimates(model = as.mitml.result(fit), extra.pars = TRUE)
```

Final parameter estimates and inferences obtained from 5 imputed data sets.

	Estimate	Std.Error	t.value	df	P(> t )	RIV	FMI
(Intercept)	5.011	0.410	12.222	4.226	0.000	35.955	0.980
sex	0.928	0.381	2.434	4.168	0.069	48.221	0.985

	Estimate
Intercept~~Intercept school	0.313
Residual~~Residual	1.428

ICC|school 0.188

Unadjusted hypothesis test as appropriate in larger samples.

### 3. Case study II: IMPACT data (syst missingness, pred matrix)

We illustrate how to impute incomplete multilevel data by means of a case study: `impact` from the **metamisc** package (empirical data on traumatic brain injuries,  $n = 11,022$  units across  $N = 15$  clusters, [Debray and de Jong 2021](#)). The `impact` data set contains traumatic brain injury data on  $n = 11022$  patients clustered in  $N = 15$  studies with the following 11 variables:

- `name` Name of the study,
- `type` Type of study (RCT: randomized controlled trial, OBS: observational cohort),
- `age` Age of the patient,
- `motor_score` Glasgow Coma Scale motor score,
- `pupil` Pupillary reactivity,
- `ct` Marshall Computerized Tomography classification,
- `hypox` Hypoxia (0=no, 1=yes),
- `hypots` Hypotension (0=no, 1=yes),
- `tsah` Traumatic subarachnoid hemorrhage (0=no, 1=yes),
- `edh` Epidural hematoma (0=no, 1=yes),
- `mort` 6-month mortality (0=alive, 1=dead).

The analysis model for this dataset is a prediction model with `mort` as the outcome. In this tutorial we'll estimate the adjusted prognostic effect of `ct` on mortality outcomes. The estimand is the adjusted odds ratio for `ct`, after including `type`, `age`, `motor_score` and `pupil` into the analysis model:

```
R> mod <- mort ~ 1 + type + age + motor_score + pupil + ct + (1 | name)
```

Note that variables `hypots`, `hypox`, `tsah` and `edh` are not part of the analysis model, and may thus serve as auxiliary variables for imputation.

The `impact` data included in the **metamisc** package is a complete data set. The original data has already been imputed once (Steyerberg et al, 2008). For the purpose of this tutorial we have induced missingness (mimicking the missing data in the original data set before imputation). The resulting incomplete data can be accessed from [zenodo link to be created](#).

Load the complete and incomplete data into the R workspace:

```
R> data("impact", package = "metamisc")      # complete data
R> dat <- read.table("link/to/the/data.txt") # incomplete data
```

The estimated effects in the complete data are visualized in Figure ??.

```
R> # fit <- glmer(mod, family = "binomial", data = impact) # fit the model
R> # tidy(fit, conf.int = TRUE, exponentiate = TRUE)      # print estimates
```

### 3.1. Missingness

To explore the missingness, it is wise to look at the missing data pattern. The ten most frequent missingness patterns are shown:

```
R> plot_pattern(dat, rotate = TRUE) # plot missingness pattern
```

This shows that we need to impute `ct` and `pupil`.

To develop the best imputation model, we need to investigate the relations between the observed values of the incomplete variables and the observed values of other variables, and the relation between the missingness indicators of the incomplete variables and the observed values of the other variables. To see whether the missingness depends on the observed values of other variables, we can test this statistically or use visual inspection (e.g. a histogram faceted by the missingness indicator).

We should impute the variables `ct` and `pupil` and any auxiliary variables we might want to

use to impute these incomplete analysis model variables. We can evaluate which variables may be useful auxiliaries by plotting the pairwise complete correlations:

```
R> plot_corr(dat, rotate = TRUE) # plot correlations
```

\*pairwise complete observations

This shows us that **hypox** and **hypot** would not be useful auxiliary variables for imputing **ct**. Depending on the minimum required correlation, **tsah** could be useful, while **edh** has the strongest correlation with **ct** out of all the variables in the data and should definitely be included in the imputation model. For the imputation of **pupil**, none of the potential auxiliary variables has a very strong relation, but **hypots** could be used. We conclude that we can exclude **hypox** from the data, since this is neither an analysis model variable nor an auxiliary variable for imputation:

```
R> dat <- select(dat, !hypox) # remove variable
```

### 3.2. Complete case analysis

As previously stated, complete case analysis lowers statistical power and may bias results. The complete case analysis estimates are:

```
R> fit <- glmer(mod, family = "binomial", data = na.omit(dat)) # fit the model
R> tidy(fit, conf.int = TRUE, exponentiate = TRUE) # print estimates
```

```
# A tibble: 11 x 9
```

	effect	group	term	estimate	std.error	statistic	p.value	conf.low	conf.high
	<chr>	<chr>	<chr>	<dbl>	<dbl>	<dbl>	<dbl>	<dbl>	<dbl>
1	fixed	<NA>	(Int~	0.0863	0.0182	-11.6	3.00e-31	0.0571	0.130
2	fixed	<NA>	type~	0.757	0.137	-1.54	1.22e- 1	0.531	1.08
3	fixed	<NA>	age	1.03	0.00265	12.9	7.40e-38	1.03	1.04
4	fixed	<NA>	moto~	0.651	0.0732	-3.82	1.34e- 4	0.522	0.811
5	fixed	<NA>	moto~	0.489	0.0555	-6.30	2.97e-10	0.391	0.611
6	fixed	<NA>	moto~	0.274	0.0321	-11.0	2.28e-28	0.218	0.345
7	fixed	<NA>	pupi~	3.20	0.317	11.7	8.18e-32	2.63	3.88
8	fixed	<NA>	pupi~	1.75	0.195	5.06	4.27e- 7	1.41	2.18
9	fixed	<NA>	ctIII	2.41	0.268	7.89	3.05e-15	1.94	2.99
10	fixed	<NA>	ctIV~	2.30	0.214	8.95	3.56e-19	1.92	2.76
11	ran_pa~	name	sd__~	0.230	NA	NA	NA	NA	NA

As we can see, a higher `ct` (Marshall Computerized Tomography classification) is associated with a lower odds of 6-month mortality, given by the odds ratio  $\exp(0.42)$ , CI ... to ..., when controlling for...

### 3.3. Imputation model

Mutate data to get the right data types for imputation (e.g. integer for clustering variable).

```
R> dat <- dat %>% mutate(across(everything(), as.integer))
```

Create a methods vector and predictor matrix, and make sure `name` is not included as predictor, but as clustering variable:

```
R> meth <- make.method(dat) # methods vector
R> pred <- quickpred(dat)   # predictor matrix
R> plot_pred(pred, rotate = TRUE)
```

```

R> pred[pred == 1] <- 2
R> pred["mort", ] <- 2
R> pred[, "mort"] <- 2
R> pred[c("name", "type", "age", "motor_score", "mort"), ] <- 0
R> pred[, "name"] <- -2
R> diag(pred) <- 0
R> plot_pred(pred, rotate = TRUE)

```

```
R> meth <- make.method(dat)
```

```
R> meth
```

```

      name      type      age motor_score      pupil      ct
      ""      ""      ""      ""      "pmm"      "pmm"
hypots      tsah      edh      mort
"pmm"      "pmm"      "pmm"      ""

```

Impute the incomplete data

```
R> imp <- mice(dat, method = meth, predictorMatrix = pred, printFlag = FALSE)
```

```
R> fit <- imp %>%
```

```
+ with(glmer(mort ~ type + age + as.factor(motor_score) + pupil + ct + (1 | name), famil
```

```
R> tidy(pool(fit))
```

	term	estimate	std.error	statistic	p.value

#### 4. Case study III: obesity data

In this example, we demonstrate a multilevel imputation of an intercept and slope random model with a continuous response. We utilize the obesity dataset included in the `micemd` package, a simulated dataset that emulates an electronic survey in which individuals are asked to provide information about their weight and consumption habits in different countries. To ease the explanations we simulate data for 5 clusters and we reduce the dataset to the following variables:

- `region` Cluster variable,
- `gender` Gender (0=male, 1=female),
- `age` Age of the patient,
- `height` Height in meters,
- `weight` Weight in kilograms,
- ‘time’ Response time in minutes (inclusion-restriction variable).
- ‘FamOb’ Family obesity history (yes or not)

Age and FamOb are missing according to a Missing At Random (MAR) mechanism, whereas the weight variable is subject to selection bias, following an indirect Missing Not At Random (MNAR) mechanism, that usually happens when it is unobserved or omitted a variable affecting both the value of incomplete variable (here weight) and its probability of missing.

The analysis model considers BMI as the dependent variable, predicted by Age, Height, Gender, and FAV. Random slopes are considered for the Age variable, which contains missing values.

The model is represented as:

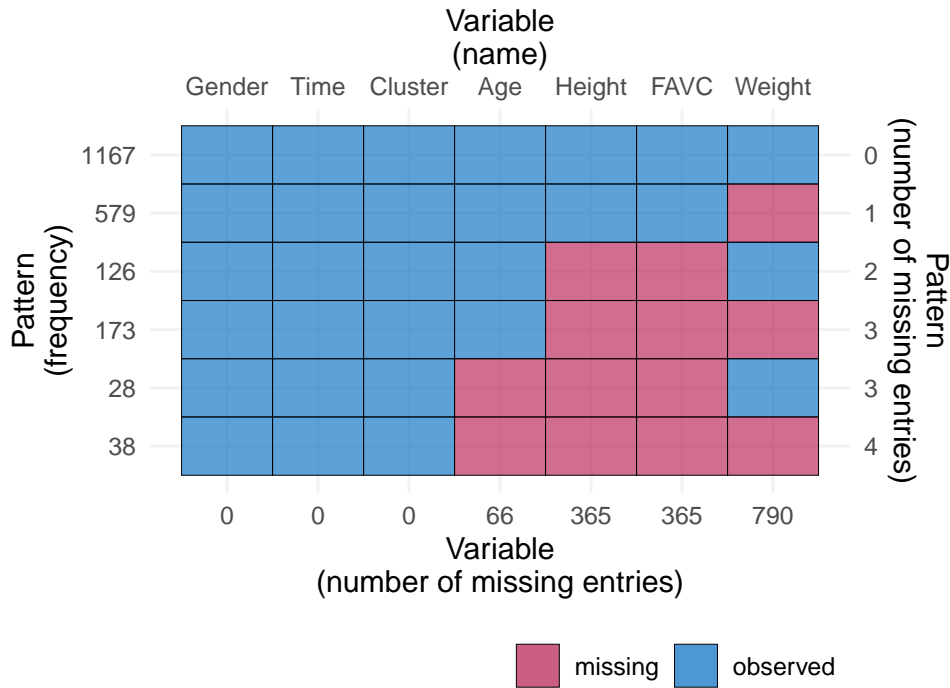

$$BMI_{ij} = (\beta_0 + b_{0j}) + (\beta_1 + b_{1j}) * Age_{ij} + \beta_2 * FAV_{ij} + \beta_3 Gender_{ij} + \epsilon_{ij}$$

We load the data:

```
R> data("data_heckman", package = "micemd")
R> dat <- data_heckman
```

Now, let's begin by examining the missing patterns in the data by cluster:

```
R> plot_pattern(dat)
```

We observe that the proportion of missingness for the Age and FAVC variables is quite similar across the clusters. However, regarding the weight variable, we notice a heterogeneous proportion of missingness, with systematic missingness in cluster 5. In order to evaluate if it is required a imputation method for 1-level or 2-level we assess the Intraclass Correlation Coefficient (ICC) for the outcome variable, we use the “performance” package:

```
R> dat$bmi=dat$Weight/(dat$Height)^2
R> Nulmodel <- lme4::lmer(bmi ~ 1 + (1|Cluster), data = dat)
R> #Performance::ICC(Nulmodel)
```

Since the ICC is above 0.1, we decide to employ two-level (2l) imputation methods. In this imputation process, we include all predictor variables in the main model and since BMI is a composite variable. We also incorporate weight and height variables.

To determine the best imputation method for these variables, we can use the `find.defaultMethod` function provided in the `micemd` package, which suggests an appropriate method for MAR variables based on the type of variable, number of observations in the cluster, and number of clusters. It suggests using “2l.2stage.bin” for the FAV variable and “2l.2stage.norm” for the age and weight variables. However, after inspecting the age density plot, we consider modifying its method to “2l.2stage.ppm.” For the BMI variable, we employ deterministic imputation.

```
R> meth_mar <- find.defaultMethod(dat, ind.clust=7, I.small = 7, ni.small = 100, prop.small = 0.1)
```

For these imputation models, it is necessary to specify the prediction matrix, with the cluster variable labeled as -2 and the predictor variable labeled as 2, encompassing all variables.

After confirming convergence, we proceed to fit the main model and save the results for future use. Users are considering the possibility that the weight variable may not have been selected

randomly. It's likely that an omitted variable, like self-esteem, could influence this selection. For instance, individuals with lower self-esteem might have higher weight values, impacting their willingness to provide honest information due to embarrassment.

To address this situation, two approaches have been proposed for dealing with Missing Not at Random (MNAR) data: pattern-mixed models and selection models. Within pattern-mixed models, methods like the delta method and more advanced ones like NARFS have been suggested. In contrast, the selection model approach includes methods such as the Heckman model, which can be particularly useful in this case. Several methods, including Galimar2017, Hammon2021, and the recent Munoz method, designed for two-level data, allowing for variations in intercepts and exposure effects (random intercept and slope).

Create predictor matrix:

```
R> pred <- quickpred(dat) # predictor matrix
R> pred[, "Cluster"] <- -2 # clustering variable
R> pred[, "Weight"] <- -3 #inclusion-restriction variable
R> plot_pred(pred)
```

Set the Heckman model as imputation method:

```
R> meth <- make.method(dat) # methods vector
R> meth["weight"]<-"2l.heckman"
```

Impute the missingness:

```
R> imp <- mice(
+   dat, # dataset with missing values
+   m = 5, # number of imputations
+   maxit = 10,
+   meth = meth, #imputation method vector
+   pred = pred, #imputation predictors matrix
+   meta_method = "reml",
+   printFlag = FALSE
+ )
```

To apply the Munoz method, the weight variable should be specified as “2l.2stage.heckman” found in the micemd package. Additionally, the prediction matrix needs modification because this method involves specifying two equations: one for the outcome, describing the incomplete variable in terms of partially observed predictors (in this case, all variables from the main model), and the other for the selection model, explaining the probability of being observed based on certain variables.

TODO: explain exclusion restriction. In this specific case, it’s assumed that height does not influence selection (-4), and an exclusion restriction variable is introduced as an instrumental variable affecting selection but not the outcome. Time of response is used for this purpose, as it’s believed that subjects taking more time to complete the survey are more likely to not respond due to poor connectivity or lack of familiarity with electronic surveys (specified as -3).

After implementing these imputation procedures, it’s crucial to check for convergence. If convergence issues arise and imputed values are far from plausible, especially affecting BMI values, a post-imputation procedure is employed to constrain BMI values within a plausible range.

Then after this modification we proceed to compare the effects on the model `###Plot estimates`

The imputation of these data is based on the [IPDMA Heckman Github repo](#)

Visualize missing data pattern:

The matrix only shows the predictors for the main model, not the selection model.

## 5. Discussion

ORDER:

- summary
- congeniality, then in hierarchical models
- look whether we can fit cong. back in the main body

- alt. methods
- conclusion: mice is really easy!
- Additional levels of clustering
- More complex data types: timeseries and polynomial relationship in the clustering.
- FIML vs MI

An alternative approach to missing data is to use Full Information Maximum Likelihood (FIML). This method does not require the imputation of any missing values. Whereas MI consists of imputation, analyses and pooling steps, FIML analyses the data in a single step. When the assumptions are met the two approaches should produce equivalent results. [REF] As FIML requires specialised software, not all analyses can be performed with standard software. [REF]

- Survival / TTE, this could be put in the paragraph on congeniality

When the outcome is time-to-event, the Nelson-Aalen estimate of the time to event should be included as a covariate in the imputation model [REF]

In hierarchical datasets, clustering is a concern because the homoscedasticity in the error terms cannot be assumed across clusters and the relationship among variables may vary at different hierarchical levels. When multiple imputation is used to deal with missing data, as the imputation and analysis process is performed separately, it is necessary that imputation model being congenial with the main analysis model (Meng, 1994), e.g. if the main model accounts for the hierarchical structure also imputation model should do it (Audigier, 2021). Not including clustering into the imputation process may lead to effect estimates with smaller standard errors and inflated type I error.

There are different strategies that can be adopted in the imputation process that account for clustering: inclusion of cluster indicator variable, performing a separate imputation process for each cluster, or performing a simultaneous imputation process by using an imputation method that accounts for clustering. (Stata: <https://www.stata.com/support/faqs/statistics/clustering-and-mi-impute/>) TODO: replace ref.

The selection of each strategy depends mainly on the assumptions in the main analysis and also on the restriction of the analyzed data.

Regarding the restrictions imposed by the data, for instance, the use of cluster indicator variables is restricted in datasets where there are not many clusters and many observations per cluster (Graham, 2009). The last restriction is also required when imputations are performed on each cluster separately. When this restriction cannot be achieved, one can use an imputation model that simultaneously imputes all clusters using a hierarchical model (Allison 2002).

Under this hierarchical imputation model, observations within clusters are correlated and this correlation is modeled by a random effect so the hierarchical model can be estimated even when there are few observations per cluster. However, this strategy is best suited for balanced data (Grund, 2017) and when random effects model is appropriated, i.e. the number of clusters is adequate. (Austin, 2018).

Here it is important to evaluate the assumptions imposed by the main model, for instance by using the cluster indicator strategy may lead to bias estimates when the model is based on a hierarchical model (Taaljard,2008). Even when an imputation strategy congenial with the main model is preferred, it is important to consider whether it is appropriate for the data as a less complex imputation strategies may also lead to unbiased estimates in certain scenarios(Bailey 2020). For instance, in causal effect analysis, separately imputation may lead to smaller bias when the size of the smaller exposure cluster is large, compared with an imputation model that includes exposure-confounder interactions. (Zhang,2023).

## 8. Appendix

Table 3: Notation

Formula lme4	Details
$y \sim x1 + (1   g1)$	Fixed $x1$ predictor with random intercept varying among $g1$
$y \sim x1*x2 + (1   g1)$	Interactions of $x1$ and $x2$ only in fixed effect
$y \sim x1*x2 + (x2   g1)$	Interactions of $x1$ and $x2$ only in fixed effect with slope of $x2$ randomly varying among $g1$
$y \sim x1*x2 + (x1*x2   g1)$	variance-covariance matrix estimated only with the variance terms of intercept, slope of $x1$ , slope of $x2$ and interaction $x1*x2$
$y \sim x1*x2 + (x1   g1) + (x2   g1)$	variance-covariance matrix estimated separately, i.e, one for intercept and $x1$ and another for intercept and $x2$

Formula lme4	Details
$y \sim x1 + (x1 \mid g1)$ or $1 + x1 + (1 + x1 \mid g1)$	Fixed $x1$ with correlated random intercept and random slope of $x$
$y \sim x1 + (x1 \parallel g1)$ or $1 + x1 + (1 \mid g1) + (0 + x1 \mid g1)$	Fixed $x1$ with uncorrelated random intercept and random slope of $x1$
$y \sim (1 \mid g1) + (1 \mid g2)$	Random intercept varying among $g1$ and among $g2$ $\mid \mid y \sim (1$
